

LiftPose3D, a deep learning-based approach for transforming two-dimensional to three-dimensional poses in laboratory animals

Markerless three-dimensional (3D) pose estimation has become an indispensable tool for kinematic studies of laboratory animals. Most current methods recover 3D poses by multi-view triangulation of deep network-based two-dimensional (2D) pose estimates. However, triangulation requires multiple synchronized cameras and elaborate calibration protocols that hinder its widespread adoption in laboratory studies. Here we describe LiftPose3D, a deep network-based method that overcomes these barriers by reconstructing 3D poses from a single 2D camera view. We illustrate LiftPose3D's versatility by applying it to multiple experimental systems using flies, mice, rats and macaques, and in circumstances where 3D triangulation is impractical or impossible. Our framework achieves accurate lifting for stereotypical and nonstereotypical behaviors from different camera angles. Thus, LiftPose3D permits high-quality 3D pose estimation in the absence of complex camera arrays and tedious calibration procedures and despite occluded body parts in freely behaving animals.

To identify how actions arise from neural circuit dynamics, one must first make accurate measurements of behavior in laboratory experiments. Recent innovations in three-dimensional (3D) pose estimation promise to accelerate the discovery of these neural control principles. 3D pose estimation is typically accomplished by triangulating two-dimensional (2D) poses acquired using multiple, synchronized cameras and deep learning-based tracking algorithms^{1–9}. Triangulation requires that every tracked keypoint (body landmark) be visible from at least two synchronized cameras¹⁰ and that each camera is calibrated. These requirements are often difficult to meet in space-constrained experimental systems that also house sensory stimulation devices^{11–13}, or when video recording untethered, freely behaving animals such as fur-covered rodents¹⁴ for whom keypoints can sometimes be occluded.

Because of these challenges, most animal studies have favored 2D pose estimation using one camera^{1,2,6,15–17}. Nevertheless, 3D poses are more desirable because they eliminate a problematic camera-angle dependence that can arise during behavioral analyses³. Recent work on human pose estimation has performed ‘lifting’ of 2D poses by regressing them to a library of 3D poses^{18–21}. However, high accuracy has only recently been achieved using deep learning^{22–34}. These techniques have not been adapted to the study of animals due to the lack of large and diverse training datasets.

Here, we introduce LiftPose3D, a tool for 3D pose estimation of tethered and freely behaving laboratory animals from a single camera view. Our method builds on a neural network architecture designed to lift human poses³⁰. We develop data transformations and network training augmentation methods that enable accurate 3D pose estimation across a wide range of animals, camera angles, experimental systems and behaviors using relatively little data. We applied LiftPose3D to a series of use cases to demonstrate that (1) a library of 3D poses can be used to train our network to lift 2D poses

from one camera, with minimal constraints on camera hardware and positioning and, consequently, no calibration, (2) by aligning animal poses, our network can overcome occlusions and outliers in ground truth data and (3) pretrained networks can generalize across experimental setups using linear domain adaptation.

Results

Predicting 3D poses with a single camera at an arbitrary position. Rather than taking independent 2D keypoints as inputs, as for triangulation-based 3D pose estimation, LiftPose3D uses a deep neural network to regress an ensemble of 2D keypoints viewed from a camera—the 2D pose—to a ground truth library of 3D poses. Considering all keypoints simultaneously allows the network to learn geometric relationships intrinsic to animal poses.

First, we illustrate how this approach can reduce the number of cameras needed for 3D pose estimation on a tethered adult *Drosophila* dataset³. Here, 15 keypoints are visible from three synchronized cameras on each side of the animal (Fig. 1a). These keypoints were annotated and triangulated using DeepFly3D³. Using this dataset as a 3D pose library we trained a LiftPose3D network that lifts half-body 2D poses from any side camera without knowing the camera's orientation (Fig. 1b,c). First, we ensured that the output of LiftPose3D was translation invariant by predicting the keypoints of the respective legs relative to six ‘root’ immobile thorax-coxa joints (green circles, Fig. 1b,c). Second, to avoid the network having to learn perspective distortions, we assumed that the focal length (intrinsic matrix) of the camera and the animal-to-camera distance were known, or that one of them is large enough to assume weak perspective effects. In the latter case, we normalized 2D input poses by their Frobenius norm during both training and testing. Third, to facilitate lifting from any angle, we assumed that extrinsic matrices, which could be obtained by calibration, might also be unknown.

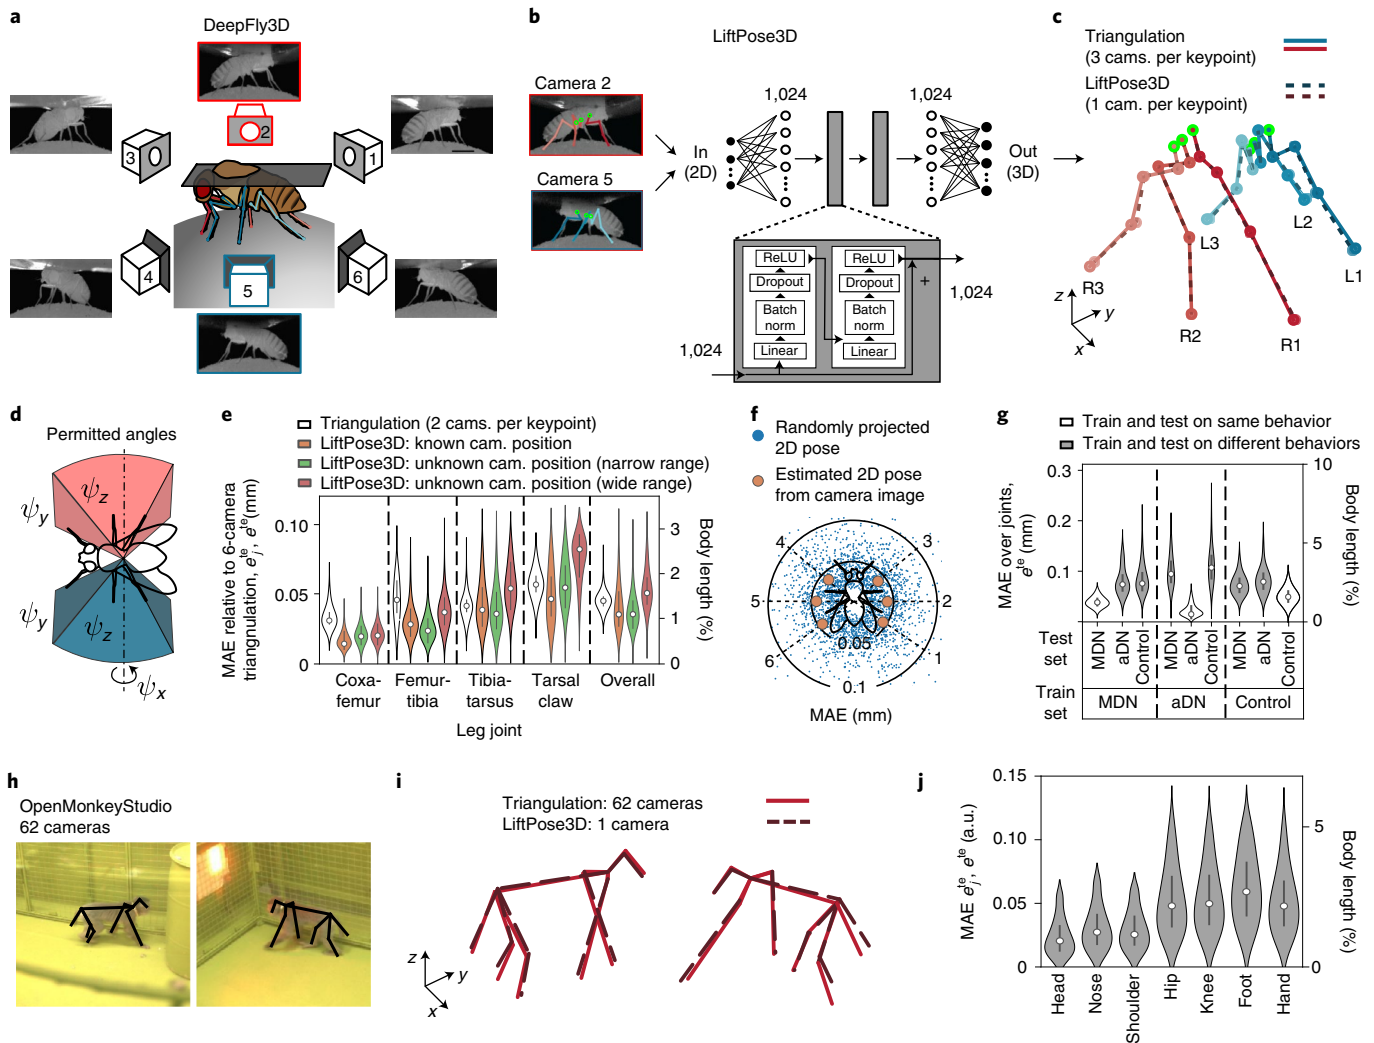

Fig. 1 | LiftPose3D predicts 3D poses with a single, flexibly positioned camera. **a**, Ground truth 3D poses of tethered *Drosophila* are triangulated using six camera views (three cameras per keypoint). **b**, LiftPose3D predicts 3D poses using deep network-derived 2D poses from only two cameras (red and blue, one camera per keypoint). The coordinates are considered relative to a set of root joints (green). The inputs are scaled up and passed twice through the main processing unit (gray rectangle) comprising batch norm, dropout and rectified linear units (ReLU) wrapped by a skip connection. **c**, The output, 3D half-body poses (blue/red), are compared with triangulated 3D poses. Limbs are labeled by position as left (L)/right (R) and front (1), mid (2) or hind (3) legs. **d**, LiftPose3D can be trained using virtual camera projections of 3D poses to lift from cameras within the angles ψ_y, ψ_z, ψ_x (representing ordered yaw, roll, pitch rotations). **e**, Error of 3D poses relative to triangulation using three cameras per keypoint. We compare triangulation error using two cameras per keypoint (white), test error for a network trained with known camera parameters (orange) and two angle-invariant networks with narrow (green, $\psi_z = \pm 10^\circ$; $\psi_y = \pm 5^\circ$; $\psi_x = \pm 5^\circ$ with respect to a known camera orientation), or wide ranges (red, $\psi_z = \pm 180^\circ$; $\psi_y = \pm 5^\circ$; $\psi_x = \pm 5^\circ$). **f**, Error of lifted 3D poses at different virtual camera orientations of the wide-range lifter network and a network with known camera parameters. Blue dots represent lifting errors for a given projected 2D pose. Orange circles represent averages over the test dataset for a given camera. **g**, Error of estimated 3D poses for a network trained and tested on different combinations of behavioral data including optogenetically induced backward walking (MDN, left), antennal grooming (aDN, middle) or spontaneous, unstimulated behaviors (control, right). **h**, Two representative images from the OpenMonkeyStudio dataset. 2D poses are superimposed (black). **i**, 3D poses obtained by triangulating up to 62 cameras (red lines), or using a single camera and LiftPose3D (dashed black lines). **j**, Absolute errors for different body parts with respect to total body length. Violin plots represent Gaussian kernel density estimates with bandwidth 0.5, truncated at the 99th percentile and superimposed with the median (gray dot), 25th and 50th percentiles (black line).

Instead, we parametrized them by Euler angles ψ_z, ψ_y, ψ_x representing ordered rotations around the z, y and x axes of a coordinate system centered around the fly (Fig. 1d). During training, we took as inputs 2D poses (from 3D poses randomly projected to virtual camera planes, rather than 2D pose estimates) and as outputs 3D poses triangulated from three cameras. To measure lifting accuracy, we tested the network on software-annotated 2D poses (Fig. 1b) from two independent animals and computed the mean absolute error (MAE), e_j^{te} , for each joint j as well as the MAE across all joints $e^{te} = (1/n) \sum_j e_j^{te}$ relative to triangulated 3D poses.

We found that LiftPose3D could predict 3D poses using only one camera per side (Fig. 1c). When the virtual projections during training were performed using known intrinsic and extrinsic matrices, the network's accuracy was at least as good as triangulation using two cameras per keypoint (Fig. 1e). The accuracy did not suffer when the network was trained using virtual 2D projections around an approximate camera location (Fig. 1e) rather than with known intrinsic matrices, or using normalized 2D poses rather than with known intrinsic matrices. Accuracy remained excellent when virtual projections extended to all possible angles around

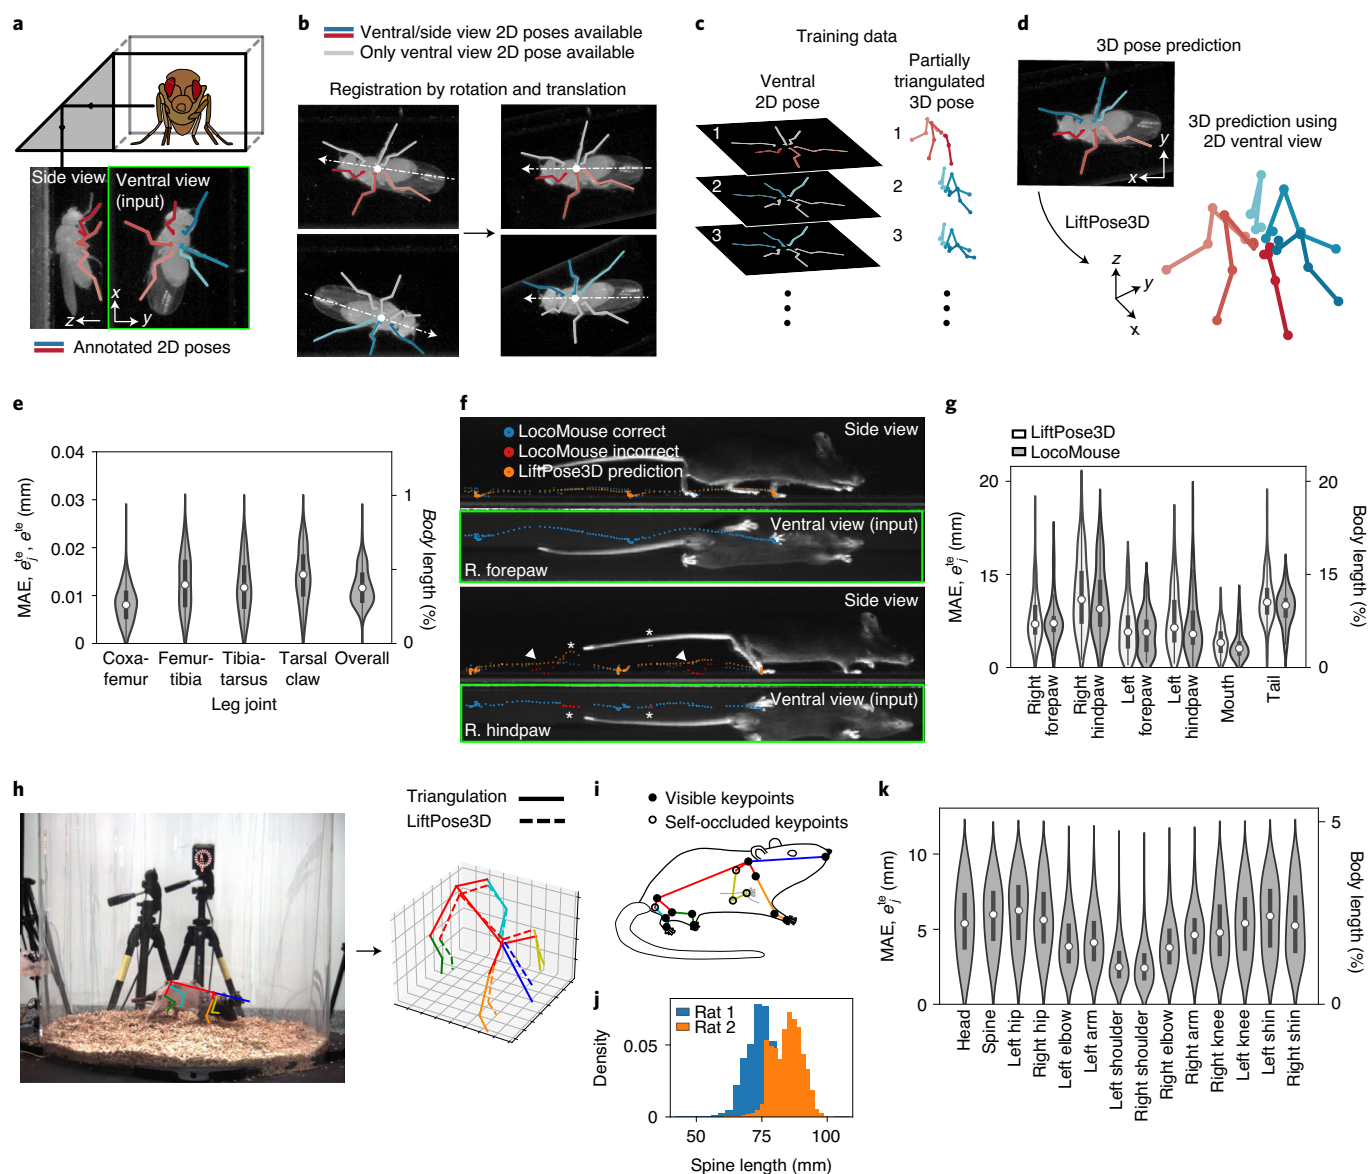

Fig. 2 | LiftPose3D performs 3D poses estimation on freely behaving animals with occluded keypoints. **a**, *Drosophila* behaving freely within a narrow, transparent enclosure. Using a right-angle prism mirror, ventral (top) and side (bottom) views are recorded with one camera. Afterward, 2D poses are annotated (colored lines). Ventral 2D poses (green box) are used to lift 3D poses. **b**, Keypoints near the prism mirror (red and blue) can be tracked in both views and triangulated. Other keypoints (gray) are only visible ventrally and thus have no 3D ground truth. Unilateral ground truths for both sides are obtained by registering the orientation and position of ventral images of the fly. **c**, Training data consist of full ventral 2D poses and their corresponding partial 3D poses. **d**, After training, LiftPose3D can predict 3D poses for new ventral view 2D poses. **e**, Joint-wise and overall absolute errors of the network's 3D pose predictions for freely behaving *Drosophila*. **f**, A similar data preprocessing approach is used to lift ventral view 2D poses of mice (green boxes) walking within a narrow enclosure and tracked using LocoMouse software. LocoMouse ground truth (blue and red) and LiftPose3D (orange) pose trajectories are shown for the right forepaw (top) and hindpaw (bottom) during one walking epoch. Arrowheads indicate where LiftPose3D lifting of the ventral view can be used to correct LocoMouse side-view tracking errors (red). Asterisks indicate where inaccuracies in the LocoMouse ventral view ground truth (red) disrupt LiftPose3D's side-view predictions (orange). **g**, Absolute errors of LiftPose3D and LocoMouse side-view predictions for six keypoints with respect to manually annotated ground truth data. **h**, Camera image from the CAPTURE dataset superimposed with the annotated 2D pose (left). LiftPose3D uses this 2D pose to recover the full 3D pose (right). **i**, LiftPose3D can be trained to lift 3D poses of a freely moving rat with occluded keypoints (open circles). **j**, Histograms of the measured lengths of the spinal segment for two different animals. **k**, Error distribution over all keypoints for the CAPTURE dataset.

the meridian (Fig. 1e). Lifting could be performed for optogenetically induced backward walking (Supplementary Video 1), antennal grooming (Supplementary Video 2) and spontaneous, irregular limb movements (Supplementary Video 3). Because the network predicts joint coordinates with respect to thoracic root joints, the MAE was larger for distal joints that move within a larger kinematic

volume. By contrast, the error for triangulation depended only on the accuracy of 2D annotations because it treats each keypoint independently. We also assessed camera-angle dependence for our wide angle-range network by lifting virtual 2D poses projected onto the meridian of the unit sphere, or 2D poses captured from each of the six cameras (Fig. 1f). The test MAE was low (<0.05 mm) and had no

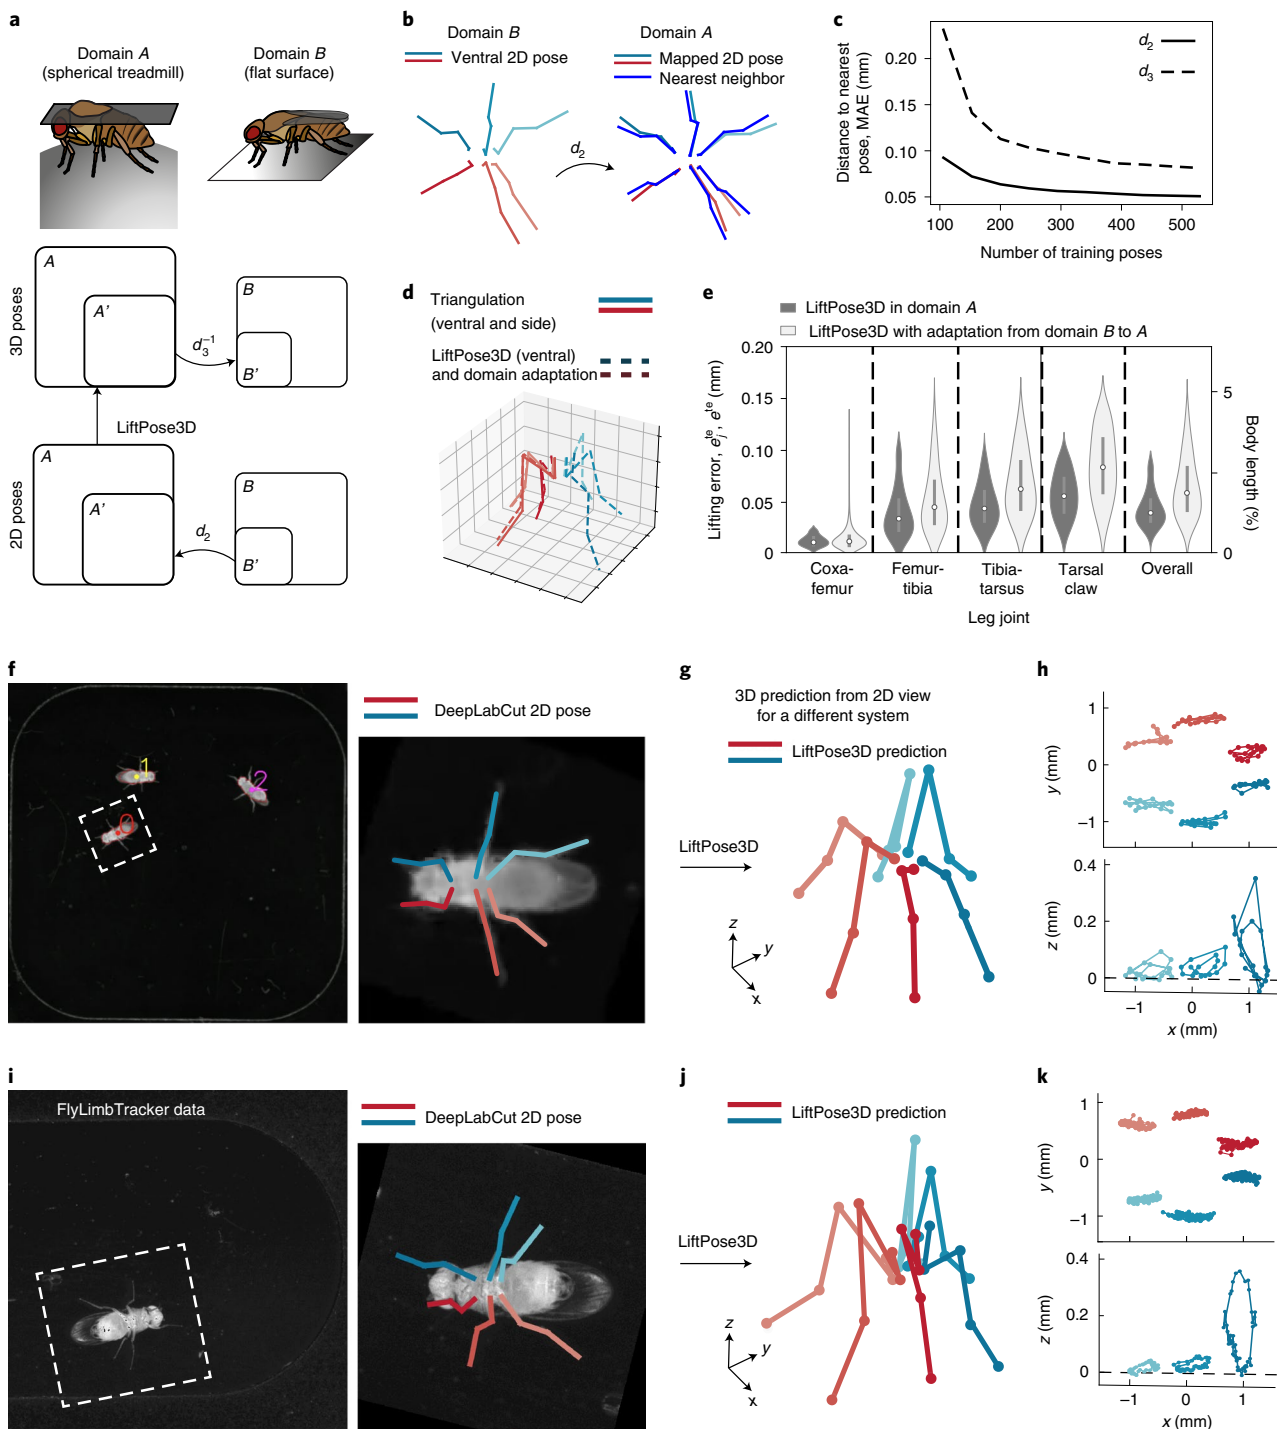

Fig. 3 | A pretrained LiftPose3D network predicts 3D poses for diverse data and when triangulation is impossible. a, Linear domain adaptation between domain A (fly on a spherical treadmill) and domain B (fly on a flat surface). 2D poses in B are mapped to A by a linear transformation d_2 then lifted with a network trained only on domain A poses. After lifting, the 3D poses are mapped back to B by another linear transformation d_3 . **b**, A typical 2D pose in domain B mapped into domain A by the best-fit linear transformation d_2 between poses in B and their nearest neighbors in A. **c**, Error between mapped pose and k nearest neighbor poses for d_2, d_3 against the number of poses used to train them ($k=1$ for d_2 and $k=2$ for d_3). **d**, Lifted 3D pose following domain adaptation of a ventral domain B 2D pose and lifting with a network trained on domain A data. The prediction is superimposed with the incomplete ground truth 3D pose in domain B. **e**, Lifting error following domain adaptation of domain B poses compared with lifting error in the domain A with no domain adaptation. **f**, Freely behaving flies were recorded from below using a low-resolution camera. Following body tracking, the region-of-interest containing the fly was cropped and registered. 2D pose estimation was then performed for 24 visible joints. **g**, 2D poses are adapted to the prism-mirror domain. These are then lifted to 3D poses using a network pretrained with prism-mirror data and coarse-grained to match the lower-resolution 2D images in the new experimental system. **h**, These 3D poses permit the analysis of claw movements in an otherwise unobserved x-z plane (bottom). **i**, Freely behaving fly recorded from below using one high-resolution camera. 2D pose estimation was performed for all 30 joints. Following tracking, a region-of-interest containing the fly was cropped and registered. **j, k**, The same LiftPose3D network trained in **b**—but without coarse graining—was used to predict 3D poses (**j**) and unobserved claw movements (**k**) in the x-z plane (bottom)¹⁶.

camera-angle dependence. Because we make no assumptions about camera placement when training our angle-invariant networks, these pretrained networks might also be used to predict accurate 3D poses for tethered *Drosophila* recorded in other laboratories.

We next explored how the similarity between animal behaviors used for training and testing might influence lifting accuracy. Our tethered *Drosophila* dataset contained optogenetically induced antennal grooming (antennal descending neurons: 'aDNs') and backward walking (moonwalker descending neurons: 'MDNs'), as well as spontaneous behaviors such as forward walking ('control'). We trained a network using poses from only one behavior (not including rest frames) and evaluated it on all three behaviors while keeping the amount of training data fixed (2.5×10^4 poses). As expected, the MAE was higher when test data included untrained behaviors than when test data included trained behaviors (Fig. 1g). Furthermore, training on all three behaviors led to comparable or lower MAE (Fig. 1e) than training and testing on one single behavior (Fig. 1g). Thus, higher training data diversity improves lifting accuracy.

To illustrate the advantage of using lifted 3D poses versus 2D poses in downstream analyses, we derived joint angles during forward walking from lifted 3D poses and from 2D poses projected from 3D poses in the ventral plane (Extended Data Fig. 1). Joint angles derived from lifted and triangulated 3D poses were in close agreement. On the other hand, when viewed from a projected plane, we found spurious dynamics in the distal joints likely due to rotations upstream in the kinematic chain (proximal joints) that cause movements of the whole leg. Thus, 3D poses predicted by LiftPose3D can help to decouple underlying physical degrees of freedom.

We also tested LiftPose3D in freely behaving animals where the effective camera angle dynamically changes, and in animals without exoskeletons whose neighboring keypoints are less constrained. Specifically, we considered freely behaving macaque monkeys⁴ where 3D poses were triangulated using 2D poses from 62 synchronized cameras (Fig. 1h). After training LiftPose3D with only 6,571 3D poses, we could lift 3D poses from test images with diverse animal poses (Supplementary Video 4), acquired from any camera (Fig. 1i) and with relatively low body length-normalized MAE (Fig. 1j).

Taken together, these results demonstrate that, using simple data preprocessing and a relatively small but diverse training dataset, LiftPose3D can reduce the number of cameras required to perform accurate 3D pose estimation.

Predicting 3D poses despite occluded keypoints. In freely behaving animals, keypoints are often missing from certain camera angles due to self-occlusions and, therefore, only partial 3D ground truth can be obtained by triangulation. We asked how the global nature of lifting—all keypoints are lifted simultaneously—might be leveraged to reconstruct information lost by occlusions, allowing one to predict full 3D poses.

To address this question, we built an experimental system similar to others used for flies and mice^{14,35,36} that consisted of a transparent enclosure coupled to a right-angle prism mirror and with a camera beneath to record ventral and side views of a freely behaving fly (Fig. 2a). Due to the right-angle prism and the long focal length camera (that is, negligible perspective effects), the ventral and side views are orthographic projections of the true 3D pose. Triangulation thus consisted of estimating the z axis depth of keypoints from the side view. Although keypoints closer to the prism were simultaneously visible in both views and could be triangulated, other joints had only ventral 2D information. We therefore aligned flies in the same reference frame in the ventral view (Fig. 2b), turning lifting into a regression problem similar to that for tethered animals. During training we took ventral view 2D poses as inputs, but trained only those keypoints with complete 3D information, that is,

those having both ventral and side views (Fig. 2c). By also aligning these data, we found that the network training converged despite the unseen coordinates (Extended Data Fig. 2), which were implicitly augmented during training by learning geometric relationships between keypoints. The network could predict 3D positions for every joint at test time, including those occluded in the side view (Fig. 2d and Supplementary Video 5). Notably, owing to the high spatial resolution of this setup, the accuracy, based on available triangulation-derived 3D positions (Fig. 2e), was better than that obtained for tethered flies triangulated using four cameras (Fig. 1e). Thus, LiftPose3D can estimate 3D poses from 2D images in cases where keypoints are occluded and cannot be triangulated.

These results indicated an opportunity to apply lifting to potentially correct inaccurate 3D poses obtained using other tracking approaches. To test this, we used a dataset consisting of freely behaving mice traversing a narrow corridor and tracked using the LocoMouse software from ventral and side views¹⁴. We triangulated and aligned incomplete 3D ground truth poses as we did for *Drosophila* and then trained a LiftPose3D network using ventral 2D poses as inputs. Predictions were in good agreement with the LocoMouse's side-view tracking (Fig. 2e and Supplementary Video 6) and could recover expected cycloid-like kinematics between strides (Fig. 2f). LiftPose3D predictions could also correct poorly labeled or missing side-view poses (Fig. 2f). However, lifting accuracy depended on the fidelity of input 2D poses: incorrect ventral 2D poses generated false side-view predictions (Fig. 2f). These errors were always localized to a single joint and were relatively infrequent. Overall, LiftPose3D and LocoMouse performed similarly compared with manual human annotation (Fig. 2g) demonstrating that LiftPose3D can be used to test the consistency of ground truth datasets.

To assess how well spatial relationships learned by LiftPose3D could generalize to animals with more complex behaviors and larger variations in body proportions, we next considered the CAPTURE dataset that was taken using six cameras that recorded freely behaving rats within a circular arena³⁷ (Fig. 2h). Animal joints were intermittently self-occluded during a variety of complex behaviors (Fig. 2i). Therefore, to allow the network to learn the skeletal geometry, we aligned animals in the camera-coordinate frame and replaced missing input data with zeros. Furthermore, to make the network robust to bone-length variability within and across animals (Fig. 2j) we assumed that bone lengths were normally distributed and generated, for each triangulated 3D pose, rescaled 3D poses by sampling from bone-length distributions while preserving joint angles. Then, we obtained corresponding 2D poses via a virtual projection within the Euler angle range of $\pm 10^\circ$ with respect to the known camera locations (to augment the range of camera-to-animal angles). Finally, we normalized 2D poses by their Frobenius norm, as before, assuming a large enough camera-to-animal distance.

To show that the network generalizes across new experimental setups, we used two experiments from this dataset (that is, two animals and two camera arrangements) for training and tested with a third experiment (a different animal, camera focal length and animal-to-camera distance). By replacing low confidence or missing coordinates with zeros, LiftPose3D could accurately predict the nonzero coordinates (Fig. 2h,k and Supplementary Video 7). Thus, this is a viable way to correct for erroneous input keypoints and makes our network directly applicable to other rat movement studies.

Lifting diverse experimental data without 3D ground truth. Although our angle-invariant networks for lifting 3D poses in tethered flies (Fig. 1d–f) and freely behaving rats (Fig. 2h–k) can be used in similar experimental systems without the need for additional training data, small variations resulting from camera distortions or postural differences may limit the accuracy of lifted poses.

Therefore, we explored how domain adaptation might enable pre-trained networks to lift poses in new experimental systems despite small postural variations.

We assessed the possibility of domain adaptation by training a network in domain A—tethered flies—and predicting 3D poses in domain B—freely moving flies (Fig. 3a). To do so, we identified two linear transformations d_2 and d_3 . d_2 is used to map 2D poses from domain B as inputs to the pretrained network in domain A, while d_3^{-1} is used to transform lifted 3D poses back to domain B. These linear transformations were found as best-fit mappings from every pose in a training dataset B' to their k nearest neighbors A' (Fig. 3b). They are expected to generalize as long as the poses in domain A are rich enough to cover the pose repertoire in domain B and are sufficiently similar between domains. We found by tenfold cross-validation that the error associated with the transformations converged after training with less than 500 poses (Fig. 3c). The final lifted poses were also in good agreement with the triangulated poses in domain B (Fig. 3d) having accuracies comparable to a network lifting purely in domain A (Fig. 3e).

To demonstrate the full potential of linear domain adaptation, we next lifted *Drosophila* 2D poses from a single ventral camera. This experimental system is common due to its simplicity, low cost and increased throughput, and has been used to study *C. elegans*³⁸, larval zebrafish³⁹, larval *Drosophila*⁴⁰, adult *Drosophila*⁴¹ and mice⁴². Because depth sensors^{43,44} cannot resolve small laboratory animals, 3D pose estimation from a single 2D view remains unsolved, but has the potential to enrich behavioral datasets and improve downstream analysis.

We developed an experimental system with a square-shaped arena in which multiple freely behaving flies were recorded ventrally using a single camera (Fig. 3f, left) at fourfold lower spatial resolution (26 px mm⁻¹) than in our prism-mirror system. We pre-trained a network using prism-mirror training data for keypoints present in both datasets and then augmented these data using a Gaussian noise term with standard deviation of roughly four. We adapted annotated 2D poses into the network's domain before lifting (Fig. 3b). We found that the network could predict physiologically realistic 3D poses in this dataset using only ventral 2D poses (Fig. 3g and Supplementary Video 8). This is remarkable because ventrally viewed swing and stance phases are difficult to distinguish, particularly at lower resolution. During walking, 2D tracking of the tarsal claws traced out stereotypical trajectories in the x - y plane⁴⁵ and circular movements in the unmeasured x - z plane (Fig. 3h). The amplitudes of these movements were consistent with real kinematic measurements during forward walking⁴⁶.

Another possibility offered by LiftPose3D is to 'resurrect' previously published 2D pose data for 3D kinematic analyses. We applied our network that was trained on prism-mirror data to lift video data of a fly walking through a capsule-shaped arena¹⁶ (Fig. 3i). Using a similar processing pipeline as before (Fig. 3b,f,g), including registration and domain adaptation but not noise perturbations (the target data were of a similarly high resolution as the training data), LiftPose3D could predict 3D poses from this dataset (Fig. 3j). We again observed physiologically realistic cyclical movements of the pretarsi during forward walking (Fig. 3k, bottom and Supplementary Video 9). These data illustrate that linear domain adaptation and LiftPose3D can be combined to lift 3D poses from previously published 2D video data for which 3D triangulation would be otherwise impossible.

***Drosophila* LiftPose3D station.** These domain adaptation results indicated that one could make 3D pose acquisition more accessible by designing a '*Drosophila* LiftPose3D station'—an open-source hardware system including a 3D printed rig supporting a rectangular arena (Extended Data Fig. 3 and Supplementary Note 1). A common hardware solution such as this overcomes potential variability

across different experimental systems that arise from camera distortions and perspective effects. Using pretrained DeepLabCut and LiftPose3D networks we found that one can effectively lift *Drosophila* 3D poses with this system (Supplementary Video 10). We envision that a similar approach might, in the future, also facilitate cross-laboratory 3D lifting of mouse 2D poses from a single camera.

Discussion

Here we have introduced LiftPose3D, a deep learning-based tool that simplifies 3D pose estimation across a wide variety of laboratory contexts. LiftPose3D can take as inputs 2D poses from any of a variety of annotation softwares^{2,3}. Through input data preprocessing, training augmentation and domain adaptation, one can train a lifting network³⁰ with several orders of magnitude less data as well as incomplete or inaccurate ground truth poses. LiftPose3D is invariant to camera hardware and positioning, making it possible to use the same networks across laboratories and experimental systems. We provide an intuitive Python notebook that serves as an interface for data preprocessing, network training, 3D predictions and data visualization.

Several factors must be considered when optimizing LiftPose3D for new experimental systems. First, because predicting depth from a 2D projection depends on comparing the lengths of body parts, input poses must be sufficiently well-resolved to discriminate between 3D poses with similar 2D projections. Second, prediction accuracy depends on training data diversity: previously untrained behaviors may not be as accurately lifted. Further work may improve LiftPose3D by constraining 3D poses using body priors⁴⁷⁻⁵¹ and temporal information³¹.

Using our domain adaptation methodology, networks with the largest and most diverse training data, such as those for the tethered fly, may be sufficiently robust to accurately lift 2D to 3D pose in other laboratories. In the future, similarly robust lifting networks might be generated for other animals through a cross-laboratory aggregation of diverse 3D pose ground truth datasets. In summary, LiftPose3D can accelerate 3D pose estimation by reducing the need for complex and expensive synchronized multi-camera systems, and arduous calibration procedures. This enables the acquisition of rich behavioral data that can advance our understanding of the neuromechanical control of behavior.

Methods

Theoretical basis for LiftPose3D. LiftPose3D estimates the 3D pose $X = (X_1, \dots, X_n)$, that is, an ensemble of 3D keypoint coordinate vectors, by learning a nonlinear mapping between triangulated ground truth 3D poses and corresponding 2D poses $x_c = (x_{c,1}, \dots, x_{c,n})$, an ensemble of 2D coordinate vectors. Formally, this operation is encoded in a lifting function f mapping a 2D pose from any camera c to their corresponding 3D pose in camera-centered coordinates, $Y_c = f(x_c)$, and a camera transformation ϕ_c , encoding a rotation and translation operation (equation (2)), mapping from camera-centered coordinates to world coordinates $X = \phi_c^{-1}(Y_c)$. The lifting function f can be approximated using a deep neural network $F(x_c; \Theta)$, where Θ represents the network weights controlling the behavior of F . In a specific application, Θ are trained by minimizing the discrepancy between 3D poses predicted by lifting from any camera and ground truth 3D poses,

$$\mathcal{J}_1(\Theta) := \sum_c \sum_{j=1}^n \chi_{V_c}(j) \| (F(x_{c,j}; \Theta))_j - Y_{c,j} \|_2^2, \quad (1)$$

where $\chi_{V_c}(j)$ is an indicator function of the set V_c of visible points from camera c . For $F(x_c; \Theta)$, we adapted a network architecture from ref. ³⁰ composed of fully connected layers regularized by batch norm and dropout⁵³ and linked with skip connections (Fig. 1b). This network was developed to perform human pose estimation following training on approximately 10^6 fully annotated 2–3D human pose pairs for many different behaviors.

Our approach implicitly assumes that the network learns two operations: lifting the 2D pose x_c to camera-centered 3D coordinates Y_c by predicting the depth component of the pose, and learning perspective effects encoded in the animal-to-camera distance and the intrinsic camera matrix (equations (2)–(5)). The intrinsic camera matrix is camera-specific, suggesting that a trained network can only lift poses from cameras used during training and that application to new settings with strong perspective effects (short focal lengths) may require camera calibration. We show that this is not necessarily the case and that one can generalize pretrained networks to new settings by weakening perspective effects. This can be accomplished by either using a large focal length camera, or by increasing the animal-to-camera distance and normalizing the scale of 2D poses.

Obtaining 3D pose ground truth data by triangulation. Triangulated 3D positions served as ground truth data for assessing the accuracy of LiftPose3D. If a keypoint j of interest is visible from at least two cameras, with corresponding 2D coordinates $x_{c,j} \in \mathbb{R}^2$ in camera c and camera parameters (extrinsic and intrinsic matrices), then its 3D coordinates $X_j \in \mathbb{R}^3$ in a global world reference frame can be obtained by triangulation. Let us express $X_j = (x_j^1, x_j^2, x_j^3)$ in homogeneous coordinates as $\hat{X}_j = (x_j^1, x_j^2, x_j^3, 1)$. The projection from the 3D points in the global coordinate system to 2D points in a local coordinate system centered on camera c is performed by the function $\pi_c: \mathbb{R}^4 \rightarrow \mathbb{R}^3$ defined as $\hat{x}_{c,j} = \pi_c(\hat{X}_j)$. This function can be expressed as a composition $\pi_c = \text{proj}_{1,2} \circ \phi_c$ of an affine transformation $\phi_c: \mathbb{R}^4 \rightarrow \mathbb{R}^4$ from global coordinates to camera-centered coordinates and a projection $\text{proj}_{1,2}: \mathbb{R}^4 \rightarrow \mathbb{R}^3$ to the first two coordinates. Both functions can be parametrized using the pinhole camera model¹⁰. On the one hand, we have

$$\phi_c(\hat{X}_j) := C_c \hat{X}_j^T = \hat{Y}_{c,j}, \quad (2)$$

where C_c is the extrinsic camera matrix corresponding to the ϕ_c and can be written

$$C_c = \begin{pmatrix} R_c & T_c \\ 0 & 1 \end{pmatrix} \quad (3)$$

as where $R_c \in \mathbb{R}^{3 \times 3}$ is a matrix corresponding to rotation around the origin and $T_c \in \mathbb{R}^3$ is a translation vector representing the distance of the origin of the world coordinate system to the camera center. Likewise, the projection function can be expressed as

$$\text{proj}_{1,2} \hat{Y}_{c,j} := K \hat{Y}_{c,j} = \hat{x}_{c,j}, \quad (4)$$

where K is the intrinsic camera transformation

$$K = \begin{pmatrix} f_x & 0 & c_x & 0 \\ 0 & f_y & c_y & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad (5)$$

where f_x, f_y denote the focal lengths and c_x, c_y denote the image center. The coordinates projected to the camera plane can be obtained by converting back to Euclidean coordinates $x_{c,j} = (\hat{x}_{c,j}^1 / \hat{x}_{c,j}^3, \hat{x}_{c,j}^2 / \hat{x}_{c,j}^3)$.

Triangulation of the coordinate X_j of joint j with respect to π_c is obtained by minimizing the reprojection error, that is, the discrepancy between the 2D camera coordinate, $x_{c,j}$, and the 3D coordinate projected to the camera frame, $\pi_c(X_j)$. Let V_c be the set of visible joints from camera c . The reprojection error for joint j is taken to be

$$e_{RP}(j; \{\pi_c\}) = \sum_c \chi_{V_c}(j) \| x_{c,j} - \pi_c(X_j) \|_2^2, \quad (6)$$

where $\chi_{V_c}(\cdot)$ is the indicator function of set V_c of visible keypoints from camera c . The camera projection functions π_c are initially unknown. To avoid having to use a calibration grid, we jointly minimize with respect to the 3D location of all joints and to the camera parameters, a procedure known as bundle adjustment¹⁰. Given a set of 2D observations, we seek

$$\min_{\pi_c, X_j} \sum_j e_{RP}(j; \{\pi_c\}) \quad (7)$$

using a second-order optimization method. For further details, we refer the interested reader to ref. ³.

LiftPose3D network architecture and optimization. The core LiftPose3D network architecture is similar to the one in ref. ³⁰ and is depicted in Fig. 1b. Its main module includes two linear layers of dimension, 1,024 rectified linear units⁵³, dropout⁵² and residual connections⁵⁴. The inputs and outputs of each block are connected during each forward pass using a skip connection. The model contains 4×10^6 trainable parameters, which are optimized by stochastic gradient descent using the Adam optimizer⁵⁵. We also perform batch normalization⁵⁶.

In all cases, the parameters were set using Kaiming initialization⁵⁴ and the optimizer was run until convergence—typically within 30 epochs—with the following training hyperparameters: batch size of 64 and an initial learning rate of 10^{-3} that was dropped by 4% every 5,000 steps. We implemented our network in PyTorch on a desktop workstation running on an Intel Core i9-7900X CPU with 32 Gb of DDR4 RAM, and a GeForce RTX 2080 Ti Dual O11G GPU. Training time was less than 10 min for all cases studied.

Weak perspective augmentation. To project 2D poses from 3D poses, one needs to know the camera transformation ϕ_c (equation (2)), encoded by the extrinsic matrix C_c (equation (3)) and the projection function $\text{proj}_{1,2}$ (equation (4)), encoded by the intrinsic matrix K (equation (5)). K may be unknown a priori at test time. Alternatively, one may want to use one of our pretrained networks on a new dataset without having to match the camera positioning (focal length, camera-to-animal distance) used to collect the training data. In this case, one may still be able to predict the 3D pose in a fixed camera-centered coordinate frame by assuming that either the camera-to-animal distance or the focal length are large enough to neglect perspective effects and by normalizing the scale of 2D poses. Following ref. ⁵⁷, we chose the Frobenius norm to perform normalization on the input 2D poses $x_{c,j} / \|x_{c,j}\|_F$, which is the diagonal distance of the smallest bounding box around the 2D pose. Note that if the 2D poses are obtained via projections, one may use the unit intrinsic matrix equation (5) with $f_x = f_y$ and $c_x = c_y = 0$ before performing normalization. Here, using $c_x = c_y = 0$ assumes that the 2D poses are centered, which in each of our examples is achieved by considering coordinates relative to root joints placed at the origin. The 2D poses must be normalized both at training and test times.

Camera-angle augmentation. The object-to-camera orientation is encoded by the extrinsic matrix C_c of equation (3). When it is unavailable, one can still use our framework by taking 3D poses from the ground truth library and, during training, performing virtual 2D projections around the approximate camera location or for all possible angles. To this end, we assume that the rotation matrix R is unknown, but that the intrinsic matrix K and the object-to-camera distance d are known such that we may take $T = (0, 0, d)^T$. When K or d are also unknown, or dynamically changing, one can make the weak perspective assumption as described in the next section. Then, instead of training the LiftPose3D network with pairs of 3D poses and 2D poses at fixed angles, we perform random 2D projections of the 3D pose to obtain virtual camera planes whose centers c_x, c_y lie on the sphere of radius d . To define the projections, we require a parametric representation of the rotations. Rotating a point in 3D space can be achieved using three consecutive rotations around the three Cartesian coordinate axes x, y, z commonly referred to as Euler angles and denoted by ψ_x, ψ_y and ψ_z . The rotation matrix can then be written as

$$R = R_{xyz} = R_x(\psi_x)R_y(\psi_y)R_z(\psi_z) \\ = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \psi_x & -\sin \psi_x \\ 0 & \sin \psi_x & \cos \psi_x \end{pmatrix} \begin{pmatrix} \cos \psi_y & 0 & \sin \psi_y \\ 0 & 1 & 0 \\ -\sin \psi_y & 0 & \cos \psi_y \end{pmatrix} \begin{pmatrix} \cos \psi_z & -\sin \psi_z & 0 \\ \sin \psi_z & \cos \psi_z & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (8)$$

Given equations (2)–(5) we may then define a random projection \hat{x}_j on the sphere of radius d of a keypoint with homogeneous coordinate \hat{X}_j as

$$\hat{x}_j = K \begin{pmatrix} R_{xyz} & T \\ 0 & 1 \end{pmatrix} \hat{X}_j \quad (9)$$

where $T = (0, 0, d)^T$. Likewise, the 3D pose in camera coordinates can be expressed as

$$\hat{Y}_j = \begin{pmatrix} R_{xyz} & T \\ 0 & 1 \end{pmatrix} \hat{X}_j. \quad (10)$$

Before training, we fix d, f_x, f_y, c_x, c_y , and define intervals for the Euler angle rotations. We then obtain the mean and standard deviation in each dimension for

both 2D and 3D poses in the training dataset by performing random projections within these angle ranges. The obtained means and standard deviations are then used to normalize both the training and test datasets.

Linear domain adaptation. Here we describe the process of adapting a network trained on data from experiment A to lift 2D poses in experiment B. Domain adaptation is also useful if the camera parameters or the distance from the camera are not known and the weak perspective assumption cannot be invoked. Before performing domain adaptation, we first estimate 2D poses from ventral images in domain B, as before. This allowed us to circumvent the difficulties arising from differences in appearance and illumination that are present in the more general image domain adaptation problem^{35,58,59}. Thus, adapting poses became a purely geometric problem of adjusting proportions and postural differences across domains.

The basis for domain adaptation is to first find a function $d_2: B|_2 \rightarrow A|_2$, where $A|_2$ and $B|_2$ are restrictions of 3D poses in the two domains, to the corresponding $2n$ -dimensional spaces of 2D poses. This function maps poses in domain B to domain A and makes them compatible inputs for the network trained on poses in domain A. In the scenario that 3D data are available in domain B, we can also find a function $d_3: B \rightarrow A$ where A and B are $3n$ -dimensional spaces of 3D poses in the two experimental domains. After 3D poses have been obtained in domain A, we map these poses back to domain B by inverting this function.

We now describe how to obtain the functions d_2 and d_3 , which we denote collectively as d . To find d , we assume that poses in domain B can be obtained by small perturbations of poses in domain A. This allows us to set up a matching between the two domains by finding nearest neighbor 2D poses in domain A for each 2D pose in domain B, $x_i^B = (x_{i,1}^B, \dots, x_{i,n}^B)$. We use 2D rather than 3D poses to find a match because 3D poses may not always be available in domain B. Moreover, the nearest poses in 3D space will necessarily be among the nearest poses in 2D space. Specifically, for each x_i^B , we find a set of k nearest poses in domain A, $\{\mathcal{N}(x_i^B)_j\}_{j=1}^k$ such that $\|\mathcal{N}(x_i^B)_j - x_i^B\|_2 < \|\mathcal{N}(x_i^B)_{j+1} - x_i^B\|_2$. We then use these poses to learn a linear mapping $W_{BA} \in \mathbb{R}^{2n \times 2n}$ from domain B to A, where n is the number of keypoints, as before. We can find this linear mapping by first defining a set of p training poses in domain B, $x_{tr}^B = (x_1^B, \dots, x_p^B)$ and writing $W_{BA}x_{tr}^B = x_{tr}^A$, where $x_{tr}^B \in \mathbb{R}^{dn \times kp}$ and $x_{tr}^A \in \mathbb{R}^{dn \times kp}$ with $d=2$ or 3 are matrices defined according to

$$W_{BA} \begin{pmatrix} | & & | & & | & & | \\ \hline x_1^B & \dots & x_1^B & \dots & x_p^B & \dots & x_p^B \\ \hline | & & | & & | & & | \\ \hline \end{pmatrix} = \begin{pmatrix} | & & | & & | & & | \\ \hline \mathcal{N}(x_1^B)_1 & \dots & \mathcal{N}(x_1^B)_k & \dots & \mathcal{N}(x_p^B)_1 & \dots & \mathcal{N}(x_p^B)_k \\ \hline | & & | & & | & & | \\ \hline \end{pmatrix} \quad (11)$$

Transposing this linear equation yields the linear problem $(x_{tr}^B)^T W_{BA}^T = (x_{tr}^A)^T$. Given that the p training poses are different, x_{tr}^B has linearly independent columns and this problem is overdetermined as long as $kp > dn$. Thus, by least-squares minimization, we obtain $W_{BA}^T = ((x_{tr}^B)^T x_{tr}^B)^{-1} (x_{tr}^B)^T (x_{tr}^A)^T$.

Experimental systems and conditions. All adult *Drosophila melanogaster* experiments were performed on female flies raised at 25 °C on a 12-h light/dark cycle at 2–3 d posteclosion. Before each experiment, wild-type animals were anesthetized using CO₂ or in ice-cooled vials and left to acclimate for 10 min. DeepFly3D tethered fly data were taken from ref. ³. OpenMonkeyStudio macaque data were taken from ref. ⁴. LocoMouse mouse data were taken from ref. ¹⁴. CAPTURE rat data were taken from ref. ³⁷. FlyLimbTracker freely behaving fly data were taken from ref. ¹⁶ (see these publications for detailed experimental procedures). For more information on the datasets including the number of keypoints, poses, animals, resolution and framerate we refer the reader to Supplementary Table 2.

Freely behaving *Drosophila* recorded from two high-resolution views using one camera and a right-angle prism mirror. We constructed a transparent arena coupled to a right-angle prism mirror³. The enclosed arena consists of three vertically stacked layers of 1/16" thick acrylic sheets laser-cut to be 15 mm long, 3 mm wide and 1.6 mm high. The arena ceiling and walls were coated with Sigmacote (Sigma-Aldrich, Merck) to discourage animals from climbing onto the walls and ceilings. One side of the enclosure was physically coupled to a right-angled prism (Thorlabs PS915). The arena and prism were placed on a kinematic mounting platform (Thorlabs KM100B/M), permitting their 3D adjustment with respect to a camera (Basler acA1920-150um) outfitted with a lens (Computar MLM3X-MP, Cary). Data were acquired using the Basler Pylon software (pylon application

v.1.2.0.8206, pylon Viewer v.6.2.0.8206). The camera was oriented vertically upward below the arena to provide two views of the fly: a direct ventral view and an indirect prism-mirror-reflected side view. The arena was illuminated by four Infrared LEDs (Thorlabs, fiber-coupled LED M850F2 with driver LEDD1B T-Cube and collimator F810SMA-780): two from above and two from below. To elicit locomotor activity, the platform was acoustically and mechanically stimulated using a mobile phone speaker. Flies were then allowed to behave freely, without optogenetic stimulation.

Freely behaving *Drosophila* recorded from one ventral view at low resolution.

We constructed a square arena consisting of three vertically stacked layers of one-sixteenth of an inch-thick (approximately 1.6 mm) acrylic sheets laser-cut to be 30 mm long, 30 mm wide and 1.6 mm high. This arena can house multiple flies at once, increasing throughput at the expense of spatial resolution (26 px mm⁻¹). Before each experiment, the arena ceiling was coated with 10 μl of Sigmacote (Sigma-Aldrich, Merck) to discourage animals from climbing onto the ceiling. A camera (pco.panda 4.2 M-USB-PCO, Gloor Instruments, with a Milvus 2/100M ZF2 lens, Zeiss) was oriented with respect to a 45° mirror below the arena to capture a ventral view of the fly. An 850-nm infrared LED ring light (CCS Inc. LDR2-74IR2-850-LA) was placed above the arena to provide illumination. Although the experiment contained optogenetically elicited behaviors interspersed with periods of spontaneous behavior, here we focused only on spontaneously generated forward walking.

The positions and orientations of individual flies were tracked using custom software including a modified version of Tracktor⁶⁰. Using these data, a 138 × 138 px image was cropped around each fly and registered for subsequent analyses.

2D pose estimation. In the prism-mirror setup, we split the data acquired from a single camera into ventral and side-view images. We hand-annotated the location of all 30 leg joints (five joints per leg) on 640 images from the ventral view and up to 15 visible unilateral joints on 640 images of the side view. We used these manual annotations to train two separate DeepLabCut 2D pose estimation networks (root-mean-squared errors for training and testing were 0.02 and 0.04 mm for ventral and side views, respectively). We ignored frames in which flies were climbing the enclosure walls (thus exhibiting large yaw and roll orientation angles). We also removed keypoints with <0.95 DeepLabCut confidence and higher than a 10-px mismatch along the x coordinate of ventral and side views. FlyLimbTracker data¹⁶ were manually annotated. Images acquired in the new low-resolution ventral view setup were annotated using DeepLabCut⁷ trained on 160 hand-annotated images. Due to the low resolution of images, the coxa-femur joints were not distinguishable. Therefore, we treated the thorax-coxa and coxa-femur joints as a single entity.

Training the LiftPose3D network. An important step in constructing LiftPose3D training data is to choose r root joints (see the specific use cases below for how these root joints were selected), and a target set corresponding to each root joint. The location of joints in the target set are predicted relative to the root joint to ensure translation invariance of the 2D poses.

The training dataset consisted of input–output pose pairs (x_c^r, X^r) with dimensionality equal to the number of keypoints visible from a given camera c minus the number of root joints r , namely $x_c^r \in \mathbb{R}^{2(|V_c|-r)}$ and $X^r \in \mathbb{R}^{3(|V_c|-r)}$. Then, the training data were standardized with respect to the mean and standard deviation of a given keypoint across all poses.

Tethered *D. melanogaster*. Of the 38 original keypoints in ref. ³, here we focused on the 30 leg joints. Specifically, for each leg we estimated 3D position for the thorax-coxa, coxa-femur, femur-tibia and tibia-tarsus joints and the tarsal tips (claws). Thus, the training data consisted of input–output coordinate pairs for 24 joints (30–6 thorax-coxa root joints) from all cameras. The training convergence is shown in Extended Data Fig. 2a.

Freely behaving macaque monkeys. The OpenMonkeyStudio dataset⁴ consists of images of freely behaving macaques inside a 2.45 × 2.45 × 2.75-m³ arena in which 62 cameras are equidistant horizontally at two heights along the arena perimeter. We extracted all five available experiments (7, 9, 9a, 9b and 11) for training and testing. Since 2D pose annotations were not available for all cameras, we augmented this dataset during training by projecting triangulated 3D poses onto cameras lacking 2D annotation using the provided camera matrix. We removed fisheye lens-related distortions of 2D poses using the provided radial distortion parameters. We normalized each 2D pose to unit length, by dividing it by its Euclidean norm as well as the 3D pose with respect to bone lengths to reduce the large-scale variability of the OpenMonkeyStudio annotations (animals ranged between 5.5 and 12 kg). We set the neck as the root joint during training. We compare our absolute errors to the total body length, calculated as the sum of the mean lengths of the nose–neck, neck–hip, hip–knee and knee–foot joint pairs. Over multiple epochs, we observed rapid convergence of our trained network (Extended Data Fig. 2b).

Freely behaving mice and *Drosophila* recorded from two views using a right-angle mirror. Freely behaving mouse data¹⁴ consisted of recordings of animals traversing a 66.5 cm long, 4.5 cm wide and 20 cm high glass corridor. A 45° mirror was used

to obtain both ventral and side views with a single camera beneath the corridor. 2D keypoint positions were previously tracked using the LocoMouse software¹⁴. We considered six main keypoints—the four paws, the proximal tail and the nose. Keypoint positions were taken relative to a virtual root keypoint placed on the ground midway between the nose and the tail. The networks were trained on partial ground truth data following pose alignment, as described in the main text. The networks for *Drosophila* and mouse training data converged within 30 and ten training epochs (Extended Data Fig. 2c,d).

Freely behaving rat in a naturalistic enclosure. The CAPTURE dataset contains recordings of freely behaving rats in a 61-cm (2-foot) diameter cylindrical enclosure video recorded using six cameras. Motion capture markers on the animal were tracked using a commercial motion capture acquisition program³⁷ to obtain 2D poses. Out of 20 possible joints, we limited our scope to the 15 joints that were not redundant and provided most of the information about the animal's pose. The dataset includes four experiments recording three rats from two different camera setups. Before using LiftPose3D, we removed the distortion from 2D poses using radial distortion parameters provided by the authors. The CAPTURE dataset has many missing 3D pose instances, which we handle by not computing the loss corresponding to these keypoints during back propagation. We selected the neck joint as the single root joint and predicted all of the other joints with respect to this root joint. We observed that LiftPose3D converged within 15 training epochs (Extended Data Fig. 2e).

Freely behaving adult *D. melanogaster* recorded from one ventral camera view. For both the newly acquired low-resolution and previously published high-resolution¹⁶ images of freely behaving flies taken using one ventral view camera, we trained a LiftPose3D network on partial ground truth data acquired from the prism-mirror system. For the high-resolution data, we considered the thorax-coxa joints as roots. For the low-resolution data, the coxa-femur joints were imperceptible. Therefore, the thorax-coxa joints were selected as roots. The training dataset consisted of coordinate pairs $(x_{\text{ventral}}^{\text{tr}} + \eta, z_{\text{side}}^{\text{tr}})$ where $x_{\text{ventral}}^{\text{tr}}$, $z_{\text{side}}^{\text{tr}}$ were chosen to represent the annotated ventral coordinates and z axis depth for the visible joints, as before. Meanwhile, η was a zero-mean Gaussian noise term with a joint-independent standard deviation of 4 px. The role of this noise term was to account for the keypoint position degeneracy inherent in the transformation from high-resolution prism training data to lower-resolution testing data. For the high-resolution dataset this noise term was set to zero.

Comparing joint angles derived from lifted 3D and 2D poses. To illustrate the benefits of using lifted 3D coordinates versus 2D coordinates for kinematic analysis, we derived the joint angles obtained from 3D coordinates along with projected 2D coordinates. Consider the (2D or 3D) coordinates of three consecutive joints in the kinematic chain of one leg with coordinates \mathbf{u} , \mathbf{v} , \mathbf{w} . Then, vectors $\mathbf{s}_1 = \mathbf{u} - \mathbf{v}$ and $\mathbf{s}_2 = \mathbf{u} - \mathbf{w}$ describe adjacent bones. Their enclosed angle is found by the cosine rule, $\cos^{-1}(\mathbf{s}_1 \cdot \mathbf{s}_2 / (|\mathbf{s}_1| |\mathbf{s}_2|))$. Due to the uncertainty of 2D and 3D pose estimation, we assumed that keypoint coordinates are Gaussian distributed around the estimated coordinate. As a proxy for the variance, we took the variation of bone lengths $|\mathbf{s}_1|$ and $|\mathbf{s}_2|$ because they are expected to remain approximately constant owing to the low mechanical compliance of the fly's exoskeleton (with the exception of the flexible tarsal segments). This allowed us to predict 3D joint angles by Monte Carlo sampling (using 5×10^3 samples), drawing one sample from each of three distributions and then computing the corresponding joint angle by the cosine rule.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

The datasets used in this paper and their sources are listed in Supplementary Table 2. Data used for Figs. 1–3 and Extended Data Figs. 1 and 2 can be downloaded from <https://doi.org/10.7910/DVN/KHFAEI>. Source data are provided with this paper.

Code availability

LiftPose3D code can be installed as a pip package at <https://pypi.org/project/liftpose/>. The source code and custom software used to acquire images with the LiftPose3D station is available at <https://doi.org/10.5281/zenodo.5031774>. The code is licensed under GNU General Public License v3.0.

Extended Data Fig. 1 | Joint angles resulting from lifting compared with 3D triangulated ground truth and 2D projections. Joint angles α, β, γ , and ω for the front, mid, and hind left legs during forward walking. Shown are angles computed from 3D triangulation using DeepFly3D (blue), LiftPose3D predictions (red), and ventral 2D projections α', β', γ' , and ω' (green). The mean (solid lines) and standard deviation of joint error distributions (transparency) are shown. Joint angles were computed by Monte Carlo sampling and errors were computed by taking the fluctuation in bone lengths.

Extended Data Fig. 2 | Training and test loss convergence of the LiftPose3D network applied to a variety of datasets. A-E Absolute test errors of LiftPose3D for all joints as a function of optimization epoch. **A** Two-camera data of *Drosophila* on a spherical treadmill (each color denotes a different pair of diametrically opposed cameras). **B** OpenMonkeyStudio dataset (each color denotes a different training run). **C** Single-camera data of *Drosophila* behaving freely in the right-angle prism-mirror system. **D** LocoMouse dataset. **E** CAPTURE dataset.

Extended Data Fig. 3 | *Drosophila* LiftPose3D station. **A** CAD drawing of the LiftPose3D station indicating major components (color-coded). **B** Photo of the LiftPose3D station. **C** Electronic circuit for building the illumination module on a pre-fabricated prototyping board (see Supplementary Table 1), electronic components and additional wiring are indicated (color-coded). **D** Printed circuit board provided as an alternative to the pre-fabricated board for building the illumination module.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our [Editorial Policies](#) and the [Editorial Policy Checklist](#).

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a Confirmed

- The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided
Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- A description of all covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
Give P values as exact values whenever suitable.
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated

Our web collection on [statistics for biologists](#) contains articles on many of the points above.

Software and code

Policy information about [availability of computer code](#)

Data collection Recordings for the prism-mirror and ventral low resolution setups have been obtained using Basler Pylon Camera Software Suite. The custom software used to acquire images the LiftPose3D station is available at <https://github.com/NeLy-EPFL/LiftPose3D>

Data analysis The code for all analysis was written in Python 3 and is available in the GitHub repository along with a full description of use under <https://github.com/NeLy-EPFL/LiftPose3D>

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

Data can be retrieved from:
<https://doi.org/10.7910/DVN/KHFAEI>

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences Behavioural & social sciences Ecological, evolutionary & environmental sciences

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	No sample size calculation was performed. The sufficiency of the number of frames (poses) used for network training was determined based on the error relative to the ground truth dataset. We also replicated the results several times to ensure the network converges and produces equivalent results.
Data exclusions	In the prism-mirror fly data, we have selected the training data to include only frames where the fly was moving by excluding resting frames based on similarity of consecutive frames. This is to ensure that training is bias-free and that the data has sufficient diversity. In the monkey data we excluded frames with unrealistic bone lengths (hundreds of meters long). In the low-resolution ventral setup and the Drosophila LiftPose3D station we excluded frames where the fly was walking on the walls of the chamber. Exclusion criteria were pre-established.
Replication	We have now fixed initial seeds to make training deterministic. However, we have in the past repeated the network training for each experiment at least three times and obtained qualitatively similar outcomes.
Randomization	In tethered fly, mouse, rat and monkey experiments, individuals were selected at random to be part of training and test datasets. We have ensured that the quantity of training and test data (number of poses) have a 8:2 ratio. We ensured that at least two unique animals are used in training and test datasets for all experiments.
Blinding	Blinding was not applicable to this study because results were obtained from automated computational data analysis rather than manual examination of the data.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Animals and other organisms

Policy information about [studies involving animals](#); [ARRIVE guidelines](#) recommended for reporting animal research

Laboratory animals	Drosophila melanogaster female flies were used raised at 25°C on a 12 h light/dark cycle at 2-3 days post-eclosion.
Wild animals	No wild animals were used in this study.
Field-collected samples	No field-collected samples were used in this study.
Ethics oversight	Drosophila melanogaster studies were performed in accordance with an institutional authorization by Swiss national authorities (A120851-21)

Note that full information on the approval of the study protocol must also be provided in the manuscript.
